### 1 INTRODUCTION

Aortic stenosis (AoS) is currently one of the most common valve diseases, a reality that is related to the progressive increase in average life expectancy (COFFEY et al, 2021). Among individuals with AoS, about 40-50% have no symptoms (PELLIKKA et al, 2005). This absence of symptoms is related to compensatory mechanisms that initially allow sufficient ventricular function. The long-term outcome involves ventricular remodeling, with hypertrophy and fibrosis of the myocardium (MAGNE et al, 2019).

AoS does not have a single form of presentation. The phenotype can be diverse, impacting the timing at which symptoms appear, and this can occur before ventricular dysfunction or the threshold definition of severe AoS (CASACLANG-VERZOSA et al, 2019).

Currently, aortic valve replacement is recommended in severe AoS, regardless of the presence or absence of symptoms, with a left ventricular ejection fraction (LVEF) below 50% (BAUMGARTNER et al, 2017). In any case, the absence of symptoms and decreased LVEF are rarely concomitant. Most commonly, symptoms arise even with preserved LVEF (DAHL et al, 2015).

Although the LVEF is an important parameter in the context of cardiac performance evaluation, it is dependent on pre- and afterload, and may not faithfully portray the quality of systole. Left ventricular hypertrophy (LVH), a consequence of AoS, can confound the value of LVEF, which can show normal values throughout the natural history of the disease, even when fibrosis and longitudinal dysfunction are already present (PONIKOWSKI et al, 2016; HERRMANN et al, 2011).

Currently, there is awareness that normal LVEF does not exclude the existence of a problem requiring early therapy, avoiding adverse events or irreversible damage to the myocardium. The study of myocardial deformation, particularly Left Ventricular Longitudinal Strain (LLS), has been shown to be an important ally in the diagnosis of early changes in ventricular function, especially when compared with conventional echocardiographic parameters (KALAM et al, 2014; WANG et al, 2022).

The portrayal of myocardial strain allows the assessment of muscle fiber contractile function even before the deterioration of LVEF, which only takes into account the difference in ventricular chamber size at end-diastole and end-systole (NESBITT et al, 2009).

Because of the impact this knowledge has on therapeutic decision making, the interest in this topic is unavoidable, accompanied by a growing number of related investigations.

## **2 OBJECTIVE**

The aim of this systematic literature review is to evaluate the incremental value of GLS, compared to conventional echocardiographic parameters, in assessing early, subclinical systolic dysfunction in patients with AoS, anticipating diagnosis and treatment.

## **3 METHODOLOGY**

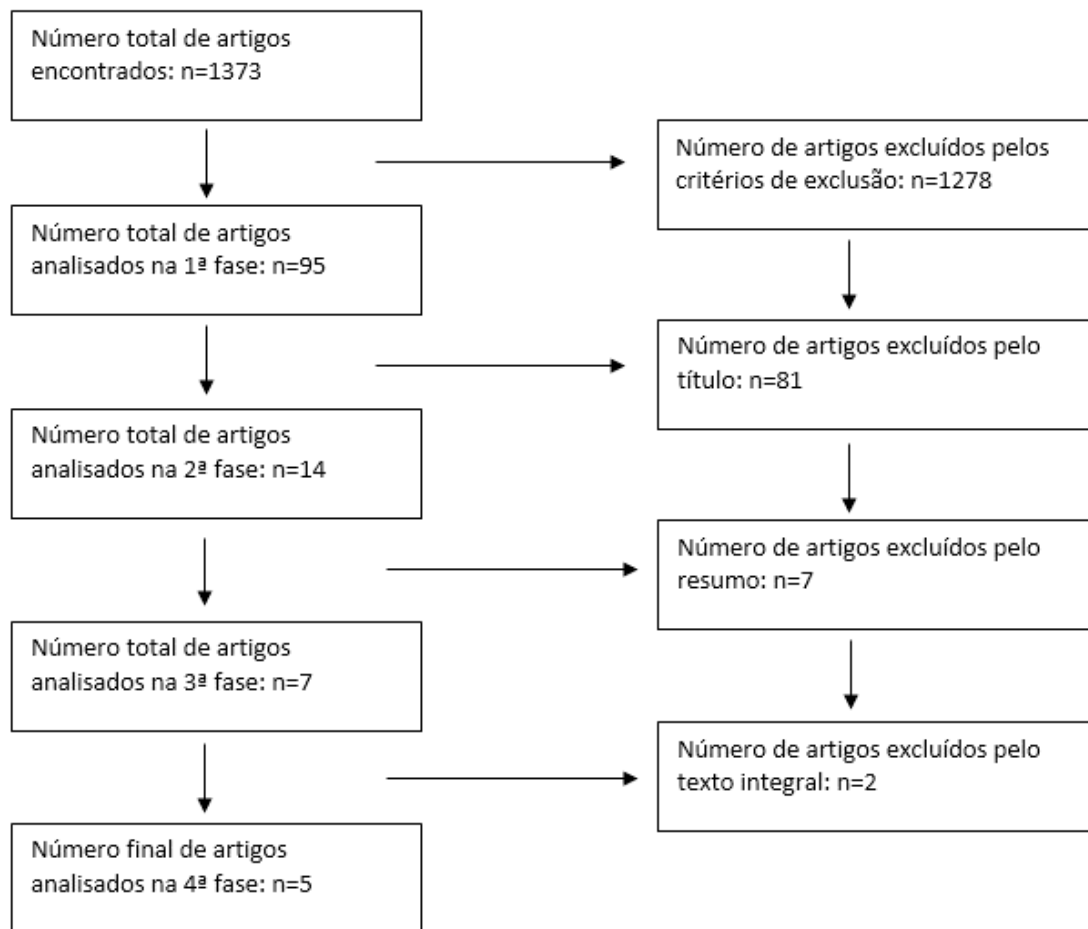

This document reflects an RSL, which followed the guidelines of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). The search for information was based on the analysis of scientific articles indexed in MEDLINE (via PubMed). For this, the following keywords were used: "strain and aortic stenosis". For each set of keywords, clinical studies and clinical trials were included, and review articles, letters to the editor, and clinical cases were excluded. Filters were also set for articles in English, Portuguese, or Spanish that had been published 10 years or less ago and that reflected results in the human species.

In a first phase, the articles were selected based on the title. After this first selection phase, the abstract of the articles resulting from the first phase was analyzed. Here we excluded all articles whose abstract demonstrated an inadequate objective or methodology for the theme. The full text was then read, and those whose information was not pertinent to the present RSL were eliminated. Here the major inclusion criterion was: studies that estimated to demonstrate the importance of GLS in the prognosis of patients with AoS. In order to decrease bias, articles that focused on specific groups of individuals with other associated known comorbidities, namely coronary artery disease, were excluded.

Of the 1373 articles that resulted from the initial search, using the aforementioned keywords, 1278 were excluded by the exclusion criteria. Then, 81 articles were eliminated by reading the title, leaving 14 articles with potential interest. After reading the abstract, the number of articles was reduced to 7, which became 5 by reading the full text, as described in Diagram 1.

PRISMA

## 4 RESULTS

The corpus of the present SLR includes 5 final articles that were included because they met all the predefined inclusion criteria. Table 1 shows information regarding the year of publication, authors, type of study, and objective(s) for each article. All articles are written and published in English and reflect results from different populations and age groups.

In common they had the main objective - to study patients with moderate or severe AoS with preserved ejection fraction, and to assess what role and impact GLS plays in distinguishing between different levels of disease severity and/or on possible outcomes in patients over a given period of time.

Table 2 summarizes the methodology, results and conclusions of each of the selected articles. It should be noted that the methodology differed between each of the 5 articles, although in all of them, patients were evaluated using the same diagnostic method - echocardiography (2D and/or 3D).

Sato et al. (2014), who aimed to evaluate whether LV GLS was able to help discriminate between different outcomes in patients with paradoxical severe AoS with low flow and low gradient, concluded that GLS, achieved using speckle tracking, has predictive value in patients with severe AoS with low flow and low gradient, patients considered to be at high risk.

Nagata et al. (2015), in turn, wanted to determine which measurement of LV GLS, by 2D or 3D echocardiography, is more reliable in predicting major adverse cardiac events in patients with AoS. In asymptomatic patients with AoS and preserved LVEF, the results allowed for the conclusion that GLS, obtained by 3D echocardiography, is the independent predictor with the most impact on the development of future major adverse cardiac complications. However, the GLS resulting from 2D echocardiography showed important predictive ability relative to conventional echocardiography.

Salaun et al. (2018) estimated to evaluate the value of LV GLS, in apical 4-chamber (4C), in the prognosis of patients with AoS. The results showed that the longitudinal strain value, obtained in the apical 4C window, is related to the percentage of deaths in patients with AoS and preserved LVEF. The evaluation and grading of AoS should, however, take into account the flow and gradient through the aortic valve orifice, since in this study, the strain cutoff value is only valid for severe AoS patients with normal flow and high gradient. In patients with AoS and preserved LVEF, the longitudinal strain value in apical 4C should therefore be used for reliable assessment of left ventricular function and prognosis of the pathology, in addition to the flow-gradient classification, a parameter that is also mandatory in these cases.

Bi et al. (2020) aimed to assess the impact of severe AoS and its consequent increase in left ventricular afterload, myocardial strain and rotation mechanisms by 2D and 3D echocardiographic speckle tracking. They concluded that in patients with severe AoS, GLS and radial strain are decreased. Circumferential strain, basal rotation and torsional motion are, in turn, increased with likely effect on normalization of cardiac output and LVEF. These facts are confirmed on 2D and 3D ultrasound by speckle tracking. The deformation of myocardial fibers, with a consequent decrease in GLS is apparently related to the increase in LV preload and afterload. They were thus able to confirm the importance of studying myocardial deformation in patients with severe AoS and preserved LVEF.

Anwer et al. (2021) had as their main objective to investigate the existing changes in routine echocardiography and strain in patients with moderate to severe AoS during a 6-month follow-up period. The left atrium was shown to be the first cavity to undergo changes, dilating, in patients with low-flow and gradient AoS, even when LV systolic-diastolic structure and function remain intact. GLS has been shown to be determinant in the assessment of LV systolic function and degree of LV diastolic dysfunction.

Table 1 - Year and author, title and objective of the investigations included in this RSL

	<b>Year and author</b>	<b>Title</b>	<b>Study Type</b>	<b>Goal</b>
1	<b>2014</b> Kimi Sato, Yoshihiro Seo, Tomoko Ishizu, Masaaki Takeuchi, Masaki Izumo, Kengo Suzuki, Eiji Yamashita, Shigeru Oshima, Yoshihiro J. Akashi, Yutaka Otsuji, Kazutaka Aonuma. 5	<ul style="list-style-type: none"><li>- A total of 197 patients with a valve area &lt;1.5cm were studied ;<sup>2</sup></li><li>- All had 2 echocardiograms, 1 baseline and one after 6 months of follow-up, according to ESC/EACTS guidelines for valve disease;</li><li>- Patients subdivided into: patients with AoS and preserved LVEF (subdivided into severe or moderate AoS) and low-flow, low-gradient AoS (LFLG).</li></ul>	<ul style="list-style-type: none"><li>- GLS decreased after 6 months of follow-up;</li><li>- LA volume increased relative to baseline echocardiogram;</li><li>- LV diameter and mass increased on follow-up echocardiogram;</li><li>- LV systolic pressure was statistically significantly higher after 6 months;</li><li>- Patients in the LFLG group had statistically lower GLS;</li><li>- There was no significant difference in LV diastolic function in the two groups;</li><li>- RV systolic pressure was higher in the LFLG group;</li><li>- There was no significant difference in GLS between patients with moderate or severe AoS;</li><li>- LA dilatation is the first change to occur in patients with LFLG EAo even with preserved LV systolic and diastolic dimensions and function;</li><li>- GLS is an important marker of LV systolic and diastolic function;</li><li>- RV function is an important parameter in the evaluation of AoS.</li></ul>

## 5 DISCUSSION

This systematic review of the literature, which gathered 5 investigations that included a total of 1560 individuals, suggests that the GLS when compared with the classical LVEF quantification, informs in advance about subclinical changes in myocardial mechanics. The GLS has, therefore, great prognostic utility in asymptomatic populations with AoS, allowing to anticipate therapeutic decision making, providing information that would hardly be available otherwise.

The most recent European and American recommendations limit surgery in severe AoS, regardless of symptomatology, to an LVEF of less than 50% (BAUMGARTNER et al, 2017; NISHIMURA et al, 2017)

Although LVEF has in itself important prognostic information, it is load-dependent and not a faithful index of myocardial contractility. The alteration in ventricular geometry, with the presence of hypertrophy, contributes to the fact that the parameter may remain within the normal range until the final stage of the disease, even if myocardial fibrosis and longitudinal dysfunction are already present. LVEF does not follow the progressive severity of AoS, whereas, in turn, GLS progressively degrades as the disease progresses (PONIKOWSKI et al, 2016; HERRMANN et al, 2011).

Also the concept of paradoxical AoS, with low flow/low gradient, has to be taken into consideration in this context. It is estimated to represent about 5 to 10% of cases of AoS (BARTKO et al, 2013). In these cases, the functional area of the aortic valve is reduced, but paradoxically the mean transvalvular gradient and systolic ejection volume are low, yet they have preserved LVEF. Inconsistency in the application of the continuity equation, a method used in echocardiography to calculate the aortic valve area, may lead to errors since it is an indirect measurement, which in turn may be at the origin of this paradox. Failure to index valve area to body surface area can also influence diagnosis (CAVACA et al, 2017). The non-existence of a significant transvalvular gradient can shift the focus to LVEF, and this parameter too can misrepresent the severity of the problem. GLS can help make a more assertive diagnostic approach in these cases.

Studies using cardiac magnetic resonance imaging describe changes in the myocardium in individuals with various stages of AoS, despite preserved LVEF (CHIN et al, 2017; BARONE-ROCHETTE et al, 2014). Many studies have found that myocardial contractility of longitudinal fibers appears earlier, which eludes LVEF quantification (DONAL et al, 2009; NG et al, 2011; LANCELLOTTI et al, 2010).

The study of histological processes, allow us to realize that the extent of hypertrophy and myocardial fibrosis is strongly related to the decrease in myocardial mechanics, assessed by GLS (MÁTYÁS et al, 2018). The pressure overload, imposed by AoS, has as its main structural consequence the development of LVH, as an adaptive response to this same pressure increase. Simultaneously, ventricular chamber volumes are smaller, resulting this context in normal LVEF, which may mask a decreased longitudinal strain (STOKKE et al, 2017).

Changes in LV longitudinal function are a consequence of AoS. The study of longitudinal function allows monitoring of disease progression, since its degradation accompanies changes in LV geometry and proliferation of myocardial fibrosis (WEIDEMANN et al, 2009; NG et al, 2011).

For this reason, current scientific evidence highlights the fact that LVEF is an insufficient parameter that can distort the perception of the quality of systolic ventricular function, and this has an influence on the timing of the implementation of appropriate therapy (BARONE-ROCHETTE et al, 2014; MENG et al, 2021). A recent study found that 13.1% of deaths occurred in individuals without significant LVEF compromise, who did not meet the current criteria in the recommendations and were not subjected to adequate therapy (NG et al, 2018).

Myocardial fibrosis develops early in a pressure overload scenario, as is the case with AoS. The establishment of fibrosis is progressive and may reach a point of no return, i.e., irreversible. This awareness alerts to the fact of the importance of assertive diagnosis and the implementation of adjusted therapy, relieving the pressure overload and allowing the regression of the fibrotic process (RUPPERT et al, 2019).

Speckle tracking is a modality of echocardiography that allows the assessment of the quality of myocardial deformation (MOR-AVI et al, 2011). It is now well established that the quantification of GLS is of tremendous interest in the context of valvular heart disease. GLS has numerous advantages, yet it remains dependent on afterload and geometry, which highlights the need to analyze some cases with extra care. The GLS, by integrating functional (contractility), hemodynamic (afterload) and also morphological (hypertrophy and fibrosis) factors, is profiled as an effective method with a huge potential to be part of the echocardiographic study in individuals with AoS (MAGNE et al, 2019).

In AoS, the GLS is compromised and can be seen as a predictor of adverse cardiac events, predicting the progression to heart failure, even in asymptomatic individuals. Fibrosis can be seen as the main factor influencing the decrease in GLS, which not being taken into account when evaluating LVEF makes it perceived that symptom-free individuals are highly benefited by its use (MAGNE et al, 2019).

Also, increased LV mechanical dispersion, which reflects intraventricular mechanical dyssynchrony and can be assessed with Speckle Tracking, is associated with adverse outcomes in individuals with AoS, regardless of LVEF (KLAEBØE et al, 2017).

Regarding the clinical repercussion of the implementation of the use of GLS in individuals with AoS, the evidence seems to point to a tendency for an earlier diagnosis of subclinical alterations, with impact on the therapeutic decision making. Two review articles concluded that with GLS values lower than 14.7%, a defined cut-off value, a marked increase in mortality or decreased quality of life seems to occur, even when LVEF is normal (WANG et al, 2022; MAGNE et al, 2019).

Although the GLS obtained using 3D echocardiography has demonstrated advantages, we are still not close to a scenario where even 2D Speckle Tracking is used in the routine of most hospitals. Even so, the predictable impact of the use of GLS for an assertive diagnosis, which prevents the progression of the disease to an irreversible stage, accompanied by a decrease in mortality and associated morbidity, cannot but draw attention to the need to consider the possibility of including Speckle Tracking evaluation of individuals with AoS in the next recommendations, regardless of the stage of the disease. The economic impact can also be taken into consideration, since successive hospitalizations can be avoided among individuals with AoS, with apparently normal function, but already with reduced GLS.

## 6 LIMITATIONS

Two staff members were involved in the screening, data extraction and analysis of the articles, and the protocol for this purpose was established according to PRISMA recommendations. However, the protocol was not published, which can be seen as a limitation of this RSL. The search was

performed in only one bibliographic database, PubMed/MEDLINE. The quality assessment of the studies was not performed by anyone outside the team.

## 7 CONCLUSIONS

GLS provides additional information of extraordinary relevance in the study of individuals with AoS, regardless of the presence or absence of symptoms, LVEF value or stenosis severity. Cases of AoS with low flow/low gradient also benefit from the use of GLS. Given its potential in risk stratification in this type of patients, its introduction in the algorithms that guide their assessment is recommended.
